Phytotoxicology Assessment Surveys Conducted in the Vicinity of Canada Brick (CB), Burlington -1986, 1987 & 1989

Introduction

Surveys were conducted by the Phytotoxicolgy Section, Air Resources Branch, in August 1986, 1987, and 1989 in the vicinity of Canada Brick (CB), Burlington, to determine the effects of fluoride emissions on surrounding vegetation. The surveys were requested by the Ontario Ministry of the Environment Central region in consideration of the potential emissions created through expansion of brick production facilities by the company in late 1986 through mid-1987. Vegetation assessment surveys had previously been conducted in 1976 and 1977, when the plant was operated by Diamond Clay Products. The earlier surveys revealed that fluoride emissions from the kilns were of minor significance.

CB lies adjacent to the Bronte River Valley at its east and north boundaries. The west boundary borders CNR tracks and is neighboured to the immediate west by scrub land and commercial/industrial properties. Neighbouring the southern boundary were commercial and residential properties abutting on Dundas St. (see attached figure).

Sampling and Injury Assessment

In August each year, tree foliage sites close to the CB company as well as at more remote sites was collected for analysis. In 1986, foliage was collected from exposed middle branches of trees available at the 8 original sites (Sites 2, 3, 4, 6, 7, 8, 9 & 12) sampled in 1977. In addition, samples were collected from 5 new sites (Sites 1, 5, 11, 14 & 15). Also, in 1986, forage (grass) was collected from the closest hay field (Site 13) to the neighbouring southeast of CB, as well as from remote Site 10. All sites, except Sites 1, 2 and 3, were situated off company property (see attached figure). In 1987 and 1989, the above-noted sites were again sampled, with exception of the forage sites in 1989. Each year, duplicate samples were collected at each site using standard sampling procedures.

Also, during each annual survey, foliage of trees and other vegetation (e.g. wild grape), which is known to be sensitive to fluoride, growing in the vicinity of the collection sites was inspected for fluoride injury.

The samples collected each year were returned to the Phytotoxicology Section for processing. Here, the tree foliage samples were processed on an unwashed and washed basis. All samples, including the unwashed forage samples, then were submitted

on a dry weight basis to the MOE laboratory for analysis of fluoride.

Analytical Results

Attached Table 1 shows the 1986, 1987 and 1989 August fluoride results for the unwashed samples. Also shown are the corresponding 1977 results. In each year, tree foliage results displayed a decreasing pattern with distance from the company. The highest fluoride levels were detected at Site 7 (native scrub area) to the immediate west of the company, and at Sites 2 & 3 (on company property) to the immediate east to southeast. It is also apparent that foliar fluoride levels throughout the survey area were markedly increased in 1987 and 1989, following the company expansion program, as compared to the pre-expansion 1977/1986 levels. The yearly average fluoride level for the seven original (1977) sites neighbouring CB increased in 1987 (141 ppm) and 1989 (138 ppm) by about 2.5 to 1.4 times compared to the respective averages for 1977 (40 ppm) and 1986 (57 ppm).

In comparison to the Phytotoxicology Section Upper Limit of Normal (ULN) rural guideline for fluoride in foliage (15 ppm), most foliage sites had a fluoride level greater than the guideline in all years. The highest unwashed foliar levels detected in 1987 and 1989 (269 & 290 ppm) were 17 to 18 times higher than the 15 ppm ULN guideline. Upper Limit of Normal guidelines represent the expected maximum concentration of contaminants in foliage/leaves not subject to the influence of point sources of emissions. They were derived by taking the arithmetic mean of available analytical data from uncontaminated samples and adding three standard deviations of the mean. It is stressed that these guidelines do not represent maximum desirable or allowable levels of contaminants. Concentration which exceed the guidelines are not necessarily toxic to plants, animals or man. Concentrations which are below the guidelines would not normally be considered toxic.

Attached Table 2 shows the percent of fluoride (considered to be particulate) removed by washing from the tree foliage samples collected each year. These data show considerable variability between sites and years. It is also apparent that the degree of particulate deposition at several sites was greater in 1987 than in 1986. In 1987, five sites (Sites 2, 4, 6, 8 & 12) had a particulate removal value of about 50 % or higher. The removal values for 1989 were, in most cases, markedly reduced from 1987 levels. This information must also be considered in light of climatic data as discussed later in this report.

As shown in Table 1, the unwashed grass samples collected at Site 13 (near CB) also had an increased fluoride level in 1987 (20 ppm) relative to the corresponding 1986 (8 ppm) level. The grass fluoride levels found at Site 13 also were higher than those found at more remote Site 10 in 1987 (5 ppm) and 1986 (4 ppm). The grass

fluoride level of 20 ppm also slightly exceeded the corresponding 12 ppm ULN guideline, but did not exceed the 80 ppm MOE forage criterion for any single month. The MOE fluoride criteria for forage was developed to protect animal health; therefore, even the highest forage level of 20 ppm would not be expected to pose any health threat to grazing animals.

Injury Assessment Findings

Foliar inspections in 1986, 1987 and 1989, revealed injury typical of fluoride toxicity primarily on wild grape plants. The most severe injury to wild grape was observed to the immediate east, southeast and west of the company in the area of collection Sites 1, 2, 3 and 7 (Sites 1, 2, & 3 were located on company property). The overall severity of injury to wild grape near these sites was rated as light (2-10%) to moderate (11-35%) in 1987 and 1989, as compared to trace (>0-1%) to light in 1977 and 1986. In all years, wild grape plants at more remote sites (off company property) exhibited either trace or very light foliar injury overall, with exception of those near Site 4 in 1987 which had light to moderate injury. Wild grape injury in the survey area, as well as being generally more severe in 1987 and 1989, also appeared to be slightly more extensive, as compared to the earlier years. In 1987 and 1989, fluoride-like injury was observed on wild grape foliage through to the area of Sites 11 (960m SW) and 15 (700m E), where only a few grape leaves were found to have trace or inconsequential injury.

Foliar inspections in 1987 also revealed trace to light injury typical of fluoride on choke cherry foliage and on current year's Eastern white pine needles in the vicinity of Site 1. Silver maple collection Site 3 also exhibited some leaves with trace injury in 1986, 1987 and 1989, as did silver maple at Site 12 in 1989. Also, gladiolus plants at Site 5 exhibited some leaves with light injury in 1989. Sites 5 and 12 were situated on residential properties south of Dundas Street. Other vegetation inspected annually throughout the survey area did not display any foliar injury which was considered to be attributable to fluoride emission.

Weather Data and Discussion

Attached Table 3 shows the wind and rainfall data from the nearby Oakville southeast station for June through August in 1977, 1986, 1987, and 1989. During this period each year, winds prevailed from the northwest (NW) and west (W). The total % of NW and W winds (June through August) was slightly increased in 1987 (55%) from 1986 (52%) and was reduced in 1989 (46%). Table 3 also shows that the total rain received during June-August of 1987 was greater than in other years, because of the unusually high rainfall in July. Rainfall can have a washing effect and reduce fluoride levels in foliage. However, in 1987, unlike other years, weather conditions were dry during the 2 week period preceding the foliage collection.

This dry weather, together with the activities/operations related to the company's expansion program, likely contributed to the fairly high particulate removal levels found in 1987. Table 3 also shows that 1989 had less rainfall than the other years. However, in 1989, there was a heavy rain on the day preceding the collection, which likely contributed to the particulate removal values being reduced from the 1987 levels.

In light of the preceding information, it is unlikely that weather was a primary contributor to the 2 fold increase in foliar fluoride levels that occurred in the survey area in 1987 and 1989 relative to the earlier periods. Because the increase in vegetation fluoride levels followed the company expansion program, it is suspected that the increase was more directly related to CB emissions of fluoride having increased during 1987 and 1989.

Summary

In summary, the results of recent vegetation surveys indicate that the Canada Brick expansion program in 1986/1987 resulted in an increase in ambient fluoride emissions. Vegetation fluoride levels and foliar injury increased in the survey area in 1987 and 1989, with corresponding foliar levels being increased by about 2 times relative to pre-expansion (1977 & 1986) levels. The most adverse effects, as in earlier years (1977 & 1986), were confined to the immediate area of the company.

VEGETATION COLLECTION SITES IN THE VICINITY OF CANADA BRICK (CB), BURLINGTON - AUGUST 1986, 1987 & 1989
